Combination Therapy Consisting of Ethanol and Radiofrequency Ablation for Predominantly Cystic Thyroid Nodules

H.M. Yoon, J.H. Baek, J.H. Lee, E.J. Ha, J.K. Kim, J.H. Yoon, and W.B. Kim

ABSTRACT

SUMMARY: Predominantly cystic thyroid nodules are often aspirated before radiofrequency ablation to enhance its efficacy; however internal bleeding during the aspiration is a problem. We evaluated the feasibility and safety of ethanol ablation to control internal bleeding that occurred during preparatory aspiration. Between September 2010 and August 2011, 11 of 40 predominantly cystic nodules bled internally during fluid aspiration before radiofrequency ablation. To control the bleeding, 99% ethanol was injected. The efficacy of ethanol in controlling bleeding, final nodule volume and complications were assessed. Control of the bleeding by ethanol ablation and subsequent radiofrequency ablation was feasible in all patients. Ninety-one percent (10/11) could be treated in 1 session. The mean nodule volume dropped from 17.1 to 4.3 mL ($P < .018$). There were no major complications. Ethanol ablation and radiofrequency ablation combination therapy is a feasible and safe technique for treating predominantly cystic thyroid nodules that exhibit internal bleeding during preparatory aspiration.

ABBREVIATIONS: EA = ethanol ablation; RF = radio-frequency; US = ultrasound

Benign nodular thyroid disease is common, and 15%–25% of solitary nodules are cystic or predominantly cystic on sonography.¹ Most cystic lesions are considered caused by the hemorrhage and subsequent degeneration of pre-existing nodules.² In patients with cosmetic or symptomatic problems, the initial procedure is the simple aspiration of the cystic portion; this reduces the cyst volume and aids in specific diagnosis, but it is associated with a high recurrence rate of up to 80%.^{3,4} For recurrent cases after aspiration, ethanol ablation (EA) has been attempted with good results.^{5,6}

Recently, radiofrequency (RF) ablation has been used to treat benign thyroid nodules with a low complication rate,^{7–12} including thyroid nodules with a cystic portion^{6,8} and recurrent thyroid cancers.¹³ Although EA is effective for treating cystic and predominantly cystic nodules, 5%–25% of patients are refractory to EA.

For those refractory cases, EA has been re-attempted, but with a marked decline in subsequent efficacy.^{14,15} EA has been used as a first-line treatment for cystic thyroid nodules^{6,16}; however EA as a first-line treatment is debatable for predominantly cystic thyroid nodules^{15,17,18} because the recurrence rate is >50% in these nodules with solid components of >20%.

When treating predominantly cystic nodules by thermal ablation, it is recommended that the internal fluid content be aspirated before RF or laser ablation^{6,19} because it is easier to treat decompressed small nodules than larger ones.²⁰ Internal hemorrhage can develop during the aspiration, however, and this bleeding enlarges the nodule volume and has a heat sink effect that could affect the efficacy of RF ablation.

In our clinic, predominantly cystic thyroid nodules that bled internally after aspiration were injected with ethanol, after which they were subjected to RF ablation. The aim of this study was to evaluate the feasibility and safety of EA in controlling internal bleeding during aspiration of the internal fluid of predominantly cystic thyroid nodules before RF ablation.

MATERIALS AND METHODS

Patients

This retrospective study was approved by our institutional review board. Informed consent for procedures was obtained from all patients before each procedure.

Between September 2010 and August 2011, one hundred thirty-one RF ablations of benign thyroid nodules were per-

formed in Asan Medical Center. Forty of these cases involved patients with predominantly cystic nodules whose internal fluid was aspirated before RF ablation. In 11 of these patients, each of whom had 1 nodule, the cysts bled internally during the aspiration of internal fluid, and they were enrolled in this study. We enrolled 3 men and 8 women with a mean age of 47.1 years (range, 30–69 years). All patients fulfilled the following criteria: 1) The cystic portion of the nodule exceeded 50% of the nodule volume, 2) there were thyroid nodule–related pressure symptoms or cosmetic problems, 3) the serum thyroid hormone and thyrotropin levels were within normal limits, 4) 2 separate ultrasound (US)-guided fine-needle aspirations led to a cytologically confirmed diagnosis of a benign lesion, and 5) there were no malignant features on the US examination.^{21–23}

Preablation Assessment

The US and US-guided fine-needle aspirations were performed by 2 radiologists (J.H.B. and J.H.L., who had 17 and 13 years of thyroid US experience, respectively). The US examinations were performed by using 1 of 2 US systems equipped with a linear high-frequency probe (5–14 MHz), namely, iU22 U (Philips Healthcare, Bothell, Washington) or EUB-7500 U (Hitachi Medical Systems, Tokyo, Japan). The size, volume, amount of solid component, and vascularity of each nodule were assessed. The 3 orthogonal diameters of each nodule (the largest diameter and the 2 diameters perpendicular to it) were measured, and the volume of each nodule was calculated by using the following equation: $V = \pi abc / 6$, where V is volume, a is the largest diameter, and b and c are the 2 perpendicular diameters.^{8,13,24} Under US guidance, 1 of the 2 radiologists performed fine-needle aspiration on the solid component of each nodule. At enrollment, the patients were asked to rate their symptom score on a 10-cm Visual Analog Scale (0–10). The physicians recorded a cosmetic grade (1, no palpable mass; 2, a palpable mass but no cosmetic problem; 3, cosmetic problem on swallowing only; and 4, readily detected cosmetic problem).^{6,25,26}

Procedure

All procedures were performed under US guidance. Intravenous sedatives or analgesics were not used before or during the procedure. The patients were placed in a supine position with mild neck extension. After skin sterilization and anesthesia with 2% lidocaine at the puncture site, a 16- or 18-ga needle was inserted into the cystic portion of the thyroid nodules through the isthmic area (this is the so-called transisthmic approach) to prevent leakage of fluid or ethanol.^{6,18,25} After the needle tip was placed into the cystic portion, as much of the internal fluid as possible was aspirated. If active bleeding was detected during the aspiration of the internal fluid, the aspiration was stopped and 99% ethanol was injected slowly into the cystic space to control the bleeding (On-line Video). The injected volume of ethanol corresponded to approximately 50% of the aspirated fluid volume. After 2 minutes of ethanol retention, as much of the injected ethanol as possible was removed.¹⁸ After real-time US confirmed that the bleeding had stopped, RF ablation was initiated. On the basis of previous experience, the RF ablation was performed by using a transisthmic approach and the moving-shot technique.

^{6–8,10,15,17,25–27} For this, an 18-ga 7-cm-long monopolar modified internally cooled electrode (Well-Point RF electrode; Taewoong Medical, Kimpo, Korea or VIVA; STARmed, Gyeonggi, Korea) with a 1- or 1.5-cm active tip and a 200-W RF generator (VIVA RF Generator; STARmed) was used.

When RF ablation was started with the 11 patients, echogenic bubbles developed much faster than would normally occur. This phenomenon was due to the remnants of ethanol in the nodule that had diffused into the septate cystic portion (On-line Video). The moving-shot technique used for thyroid RF ablation^{7,8,10,28–30} was first proposed by Baek et al,²⁶ who suggested that the thyroid nodule should be divided into multiple conceptual ablation units that would each undergo RF ablation; this was achieved by moving the electrode tip. Because the conceptual units are smaller at the periphery of the nodule and larger in the center of the nodule, the electrode tip was initially positioned in the deepest, most remote portion of the nodule where there were no disturbances caused by microbubbles; this positioning facilitated the monitoring of the electrode tip. RF ablation was terminated when all conceptual units of the targeted nodule had changed into a transient hyperechoic zone. Adverse events during and immediately after the procedure were recorded. After RF ablation, the patient was observed for 1–2 hours in the hospital.

Follow-Up and Analysis

At 1, 6, and 12 months after RF ablation and every 6–12 months thereafter, the clinical symptoms and cosmetic problems of all patients were re-evaluated. US examinations were also performed; changes in the amounts of the cystic portion, the internal vascularity, the echogenicity, the size, and the volume of the nodules were recorded. The efficacy of RF ablation was determined by measuring the volume reduction of the treated thyroid nodules and by assessing changes in the symptoms and cosmetic problems. Therapeutic success was defined as a nodule volume reduction >50%. Adverse events during the follow-up period were also recorded. Recurrence was defined as an increase in nodule volume by >50% relative to the volume recorded by US previously.²¹

Statistical Analysis

All statistical analyses were performed by using the Statistical Package for the Social Sciences for Windows (Version 18.0; IBM, Armonk, New York). The Wilcoxon signed rank test was used to evaluate the efficacy (changes in the largest diameter, the volume, and the cosmetic and symptom scores) of RF ablation at the 1-month, 6-month, and last follow-up visits.

RESULTS

After EA, the active bleeding stopped in all patients and US confirmed that there was no blood collection within the thyroid nodule. The efficacy of RF ablation is summarized in the Table. The mean follow-up period was 11.4 ± 6.7 months (range, 6–24 months). The mean largest diameter decreased from 4.1 ± 1.3 cm (range, 2.4–7.1 cm) before treatment to 2.3 ± 0.6 cm (range, 1.3–3.0 cm) at the last follow-up ($P = .003$), and the mean volume dropped from 17.1 ± 16.9 mL (range, 2.9–59.0 mL) to 2.6 ± 2.1

mL (range, 0.2–6.9 mL) at the last follow-up ($P = .005$). At the 1-month, 6-month, and last follow-up visits, the mean volume reduction percentages were 52.9%, 75.6%, and 81.0%, respectively. Therapeutic success was achieved in all patients. The mean cosmetic score decreased from 4.0 before treatment to 2.8 ± 1.0 (range, 1–4) at the last follow-up ($P = .01$). The mean symptom score dropped from 2.7 ± 1.5 (range, 1–5) before treatment to 1.1 ± 1.0 (range, 0–4) at the last follow-up ($P = .011$). The follow-up US examinations indicated well-treated nodules that no longer had a cystic portion and whose echogenicity of the solid portion and intranodular vascularity was decreasing (Fig 1).

The mean number of ablation sessions was 1.2 ± 0.6 (range, 1–3): Ten patients had 1 session, while the remaining patient had 3 sessions. The latter patient had a large initial thyroid nodule

volume of 37.3 mL. The mean ablation time and power were 6.3 ± 3.0 minutes (range, 3–12 minutes) and 57.3 ± 24.9 W (range, 30–120 W), respectively. The mean total energy deposition was $21,218.2 \pm 11,523.7$ J (range, 7800–36,000 J). The mean energy delivered per milliliter of pretreatment nodule volume was 2013.3 ± 1228.3 J (range, 684.2–4230.8 J). The mean volume of aspirated internal fluid was 8.8 ± 9.3 mL (range, 2–35 mL), while the mean amount of ethanol that was injected was 5.1 ± 5.7 mL (range, 1–20 mL).

There were no major complications, such as voice changes, skin burn, hematoma, esophageal injury, tracheal injury, or infection, either during the procedure or in the follow-up period. During RF ablation, most patients reported pain and a sensation of heat in the neck that radiated to the head, shoulders, teeth, and chest. The symptoms were relieved by reducing the RF power or stopping the ablation for several seconds. All patients tolerated the RF ablation procedure well.

Efficacy of ethanol and RF ablation combination therapy^a

	Initial	Last Follow-Up	P Value
Largest diameter (cm)	4.1 ± 1.3	2.3 ± 0.6	.003
Volume (mL)	17.1 ± 16.9	2.6 ± 2.1	.005
Cosmetic score	4.0 ± 0	2.8 ± 1.0	.01
Symptom score	2.7 ± 1.5	1.1 ± 1.0	.011

Therapeutic success (%) ^b	—	100	—

^a Values are means.

^b Therapeutic success is volume reduction >50%.

DISCUSSION

The present study showed that EA effectively controlled the post-aspiration hemorrhage in all patients. The RF ablation, after bleeding control was achieved, significantly reduced the nodule volume and relieved the symptomatic and cosmetic problems. In addition, 91% (10/11) of the patients could be treated by 1 RF session, and there were no recurrences during the follow-up pe-

FIG 1. A 59-year-old female patient who presented with a bulge in the neck. A, Transverse US images at presentation show a thyroid nodule with a cystic portion in the right thyroid gland. The initial volume of the nodule was 11.4 mL. B, On Doppler US, increased vascularity in the solid portion of the nodule was also noted. C and D, After active bleeding was controlled by EA and RF ablation was performed, the volume of the ablated nodule decreased gradually to 2.8 and 0.9 mL at the 6- and 12-month follow-up US examinations, respectively. At the 12-month follow-up visit, the volume had been reduced by approximately 92%.

riod. There were also no complications that related to the EA or RF ablation.

Initial nodule volume can be a risk factor for poor volume reduction by RF and the need for additional RF treatment sessions. Huh et al²⁰ reported that an initial nodule volume larger than 20 mL required additional RF ablation to achieve satisfactory clinical results. Moreover, Jeong et al⁸ reported that thyroid nodules with a mean volume of 6.1 mL required an average of 1.4 treatment sessions, while Lim et al³¹ reported that thyroid nodules with a mean volume of 9.8 mL required 2.2 treatment sessions on average. These results indicate that smaller thyroid nodules can be treated with fewer sessions. In the present study, the mean nodule volume was larger (17.1 mL) than the mean volumes in the other RF studies (6.1–9.8 mL).^{8,31} Nevertheless, 91% (10/11) of patients could be treated in a single RF session; in addition, there were no recurrences during the mean follow-up period of 11.4 months. As a result, the mean treatment session number in this study was smaller (1.2) than the numbers in other studies (1.4–2.2). The present study differed from the preceding studies in that the internal fluid was aspirated to reduce the nodule volume with the aim of reducing the number of treatment sessions. The results indicate that this approach was successful. However, active bleeding can be triggered by the aspiration, and this can create an important technical problem: It can cause sudden enlargement of the thyroid nodule and the heat sink effect of the blood can make RF ablation ineffective. The present study showed that EA successfully controlled active bleeding during aspiration and that nodule volume was effectively reduced before RF ablation.

The reduction in nodule volume after RF ablation has been found to range from 33% to 58% at 1 month and from 51% to 92% at 6 months.²⁶ Jeong et al⁸ reported that after a mean follow-up period of 12 months, the mean volume reduction was 84.1% and that 70.2% of the nodules could be treated by a single treatment session. In the present study, the mean follow-up period was 11.4 ± 6.7 months, the mean volume reduction was 81.0%, and 91% (10/11) of the nodules could be treated by a single session. Therefore, our results are comparable with those of previous studies with fewer treatment sessions. In addition, there was 100% technical success and no major complications.

RF ablation combined with EA has been used for hepatocellular carcinomas in high-risk locations, and 2 studies have shown that this combination is more effective and safe than RF ablation alone.^{32,33} In these studies, the principal role of ethanol was to induce a larger necrotic area and to minimize complications.^{34,35} To our knowledge, the present study is the first to examine the efficacy of the combination of these 2 modalities in treating predominantly cystic thyroid nodules.

The present study has several limitations. First, it had a retrospective design, but a standard technique was used to control active bleeding during the RF ablation. Second, the number of cases was small, and the follow-up period was short. Third, there was no control group. Further prospective studies are required to verify the value of the current study.

CONCLUSIONS

EA is a feasible and safe technique for controlling the active bleeding of predominantly cystic thyroid nodules that can occur when internal fluid is aspirated before RF ablation, allowing RF ablation to proceed in a single session in most instances.
