Maternal Obesity during Pregnancy is Associated with Lower Cortical Thickness in the Neonate Brain

 X. Na,  N.E. Phelan,  M.R. Tadros,  Z. Wu,  A. Andres,  T.M. Badger,  C.M. Glasier,  R.R. Ramakrishnaiah,  A.C. Rowell,  L. Wang,  G. Li,  D.K. Williams, and  X. Ou

ABSTRACT

BACKGROUND AND PURPOSE: Recent studies have suggested that maternal obesity during pregnancy is associated with differences in neurodevelopmental outcomes in children. In this study, we aimed to investigate the relationships between maternal obesity during pregnancy and neonatal brain cortical development.

MATERIALS AND METHODS: Forty-four healthy women (28 normal-weight, 16 obese) were prospectively recruited at <10 weeks' gestation, and their healthy full-term neonates (23 boys, 21 girls) underwent brain MR imaging. All pregnant women had their body composition (fat mass percentage) measured at ~12 weeks of pregnancy. All neonates were scanned at ~2 weeks of age during natural sleep without sedation, and their 3D T1-weighted images were postprocessed by the new iBEAT2.0 software. Brain MR imaging segmentation and cortical surface reconstruction and parcellation were completed using age-appropriate templates. Mean cortical thickness for 34 regions in each brain hemisphere defined by the UNC Neonatal Cortical Surface Atlas was measured, compared between groups, and correlated with maternal body fat mass percentage, controlled for neonate sex and race, postmenstrual age at MR imaging, maternal age at pregnancy, and the maternal intelligence quotient and education.

RESULTS: Neonates born to obese mothers showed significantly lower ($P \leq .05$, false discovery rate–corrected) cortical thickness in the left pars opercularis gyrus, left pars triangularis gyrus, and left rostral middle frontal gyrus. Mean cortical thickness in these frontal lobe regions negatively correlated ($R = -0.34$, $P = .04$; $R = -0.50$, $P = .001$; and $R = -0.42$, $P = .01$; respectively) with the maternal body fat mass percentage measured at early pregnancy.

CONCLUSIONS: Maternal obesity during pregnancy is associated with lower neonate brain cortical thickness in several frontal lobe regions important for language and executive functions.

ABBREVIATIONS: BMI = body mass index; FDR = false discovery rate; IQ = intelligence quotient

The most recent National Health and Nutrition Examination Survey reported that 39.7% of women in the United States 20–39 years of age are obese (body mass index [BMI], ≥ 30),¹ and the most recent national birth data showed that 54.7% of neonates in 2018 in the United States were born to overweight (BMI ≥ 25) or

obese women.² Maternal obesity during pregnancy has become a prevalent health concern, not only for the pregnant women but also for their offspring,³ including their neurodevelopment.^{4,5} Recent studies have shown negative associations between maternal obesity and neurodevelopmental outcomes of children, including reduced infant cognitive development scores, increased risk of delayed mental development, lower cognitive performance, impaired executive function, lower full-scale intelligence quotient (IQ) and verbal IQ, higher attention-deficit/hyperactivity disorder symptom scores, increased risk for inattention and negative emotionality, and higher prevalence of autism.^{4,6–18} These findings strongly suggest that maternal obesity during pregnancy can negatively influence an offspring's cognitive and neurodevelopmental outcomes. Nevertheless, little is known regarding the underlying mechanism of these associations.

Recent advances in early neuroimaging, particularly advanced and quantitative MR imaging, which can detect subtle changes in

the brain, provide a sensitive tool to detect the potential in utero effects of maternal obesity on the developing brain. These direct effects on early brain development, if observed, may link maternal obesity during pregnancy with adverse long-term neurodevelopmental outcomes in children and may shed light on the underlying mechanism. In fact, a few recent studies have reported significant changes in neonatal brain structural and functional development associated with maternal obesity. For example, neonates of obese, otherwise healthy, women showed lower brain white matter development measured by diffusion tensor imaging in widespread regions in the frontal and parietal lobes compared with neonates of healthy normal-weight women.¹⁹ Weaker functional connectivity of the dorsal anterior cingulate cortex to the prefrontal networks in neonates born to obese-versus-normal-weight women was also observed in a study using independent component analysis of resting-state fMRI data,²⁰ and a further seed-based and graph theory of functional connectivity study indicated possible neonatal functional connectivity alterations in 4 functional domains implicated in adult obesity: sensory processing, reward processing, cognitive control, and motor control.²¹ In addition, another study also observed that a higher maternal prepregnancy BMI was associated with greater local thalamic and lower frontothalamic functional connectivity in the neonatal brain.²² Furthermore, studies have also shown that brain imaging features measured by early MR imaging are associated with long-term neurodevelopmental outcomes not only in neonates with medical conditions such as prematurity, congenital heart diseases, or hypoxic-ischemic encephalopathy^{23–25} but also in neonates who are born full-term, healthy, and typically developing.²⁶ These findings suggest the importance of early neuroimaging in understanding the potential effects of maternal obesity during pregnancy on children's neurodevelopmental outcomes.

Brain cortical development starts in the first trimester of gestation and continues in the fetal and postnatal stages, with dynamic synapse formation in early life followed by gradual pruning throughout childhood. This process can be reflected by measurements of cortical thickness, which reaches a peak between 1 and 2 years of age²⁷ and starts to decrease thereafter.²⁸ Despite the obvious importance of brain cortical development in a child's brain function and cognitive outcomes, so far no published studies have evaluated whether maternal obesity during pregnancy would alter cortical development in the developing brain at early ages. In this study, we aimed to investigate relationships between maternal obesity and neonate brain cortical development. Our hypothesis was that maternal obesity during pregnancy would slow fetal cortical development and result in lower neonate cortical thickness in different brain regions. To test

our hypothesis, we enrolled healthy normal-weight and obese pregnant women at first trimester, measured their BMI and body composition, performed brain MR imaging examination on their neonates, compared cortical thickness between the 2 groups of neonates, and evaluated its relationship with maternal body fat mass percentage measured at early pregnancy.

MATERIALS AND METHODS

Subjects

Healthy pregnant women of <10 weeks' gestation and their full-term healthy neonates were included in this study. All study procedures were approved by the University of Arkansas for Medical Sciences institutional review board, and all participants provided written informed consents. Inclusion criteria for the pregnant women were the following: prepregnancy BMI of 18.5–24.9 kg/m² [normal-weight group] or 30–35 kg/m² [obese group]), second parity, singleton pregnancy, 21 years of age or older, and conceived without assisted fertility treatments. Exclusion criteria for the pregnant women were the following: pre-existing medical conditions such as diabetes mellitus, seizure disorder, and serious psychiatric disorders; drug or alcohol abuse; sexually transmitted diseases; and medical complications during pregnancy such as gestational diabetes and pre-eclampsia. In addition, neonates born preterm (<37 weeks of gestation) or with medical conditions or medications known to influence growth and development or those unable to complete a brain MR imaging examination during natural sleep were also excluded.

All pregnant women had their body composition assessed using air displacement plethysmography (BOD POD; Cosmed) and BMI measured at ~12 weeks of pregnancy at Arkansas Children's Nutrition Center. Maternal IQ was also assessed using the Wechsler Abbreviated Scale of Intelligence (Pearson). After

delivery, birth weight and the length of the neonates were retrieved from the medical records, while head circumference was measured at ~2 weeks of age during the infant's study visit. Family socioeconomic status of the neonates including parental education and income was also obtained during the mother's pregnancy visits.

In total, 44 pregnant women (28 normal-weight, 16 obese) and their neonates completed the experimental procedures and were included in this study. Table summarizes the demographic information of the study participants.

MR Imaging Data Acquisition

At ~2 weeks of age, all neonates underwent an MR imaging examination of the brain during natural sleep without sedation at the Arkansas Children's Hospital, Department of Radiology. They were fed 15–30 minutes before the scan, swaddled in warm sheets, and bundled using a MedVac Infant Immobilizer (CFI Medical Solutions). No sedation was used. A pulse oximeter probe (InVivo) was placed on a foot to monitor oxygen saturation and heart rate, and Mini Muffs (Natus Medical) and a headset were placed over the ears to protect the neonates from the noise generated during the scan. The MR imaging examinations were performed on a 1.5T Achieva MR imaging scanner (Philips Healthcare) with a 60-cm bore size, 33-mT/m gradient amplitude, and 100-mT/m/ms maximum slew rate. We used a pediatric 8-channel sensitivity encoding head coil and a neonatal brain MR imaging protocol, which included sagittal 3D turbo field echo T1-weighted imaging reconstructed to 3 planes, axial T2-weighted, axial diffusion-weighted, and axial susceptibility-weighted imaging sequences. This conventional neonatal MR imaging protocol was used for the neuroradiologists to screen subjects for incidental findings, while the 3D T1-weighted images with TR = 7.1 ms, TE = 3.2 ms, flip angle = 8°, and resolution = 1 × 1 × 1 mm were used for subsequent cortical brain morphometry analysis, particularly measurements of cortical thickness. Imaging quality control was performed on the scanner by experienced MR imaging technicians. Scans were repeated if considerable motion artifacts were present, and those neonates who woke up during the scan without a valid 3D T1 dataset were excluded from this study.

MR Imaging Data Analysis

All MR images were exported to the local PACS system from the scanner and were reviewed by one of our neuroradiologists. No incidental findings needing medical attention were noted. All of the 3D T1-weighted images were also exported to local workstations for further cortical analysis. Specifically, DICOM images were converted to NIfTI format and were postprocessed by the new iBEAT V2.0 software (Developing Brain Computing Lab and Baby Brain Mapping Lab). iBEAT V2.0 is a toolbox using advanced approaches including deep learning for processing pediatric brain T1- and T2-weighted MR images. It is an upgrade from the previous iBEAT software and has demonstrated superior capability and accuracy in infant structural MR imaging data postprocessing. For neonatal MR imaging, 3D T1-weighted images are adequate for the automated postprocessing because of the considerable contrast between different tissues. For this study, 3D T1-weighted MR images were corrected for inhomogeneity

before skull stripping,²⁹ followed by tissue segmentation to gray matter, white matter, and CSF. Left/right hemisphere separation and topology correction were then performed.^{30,31} Cortical surfaces including inner cortical and outer cortical surfaces were reconstructed. Cortical parcellation was performed on the basis of the infant developmental parcellation maps.^{27,32} The UNC Neonatal Cortical Surface Atlas,^{32,33} which parcellates the brain cortex in each hemisphere into 34 different regions, was used to calculate the mean cortical thickness for each cortical region for each neonate. Cortical thickness was defined as the closest distance from the white surface to the pial surface at each vertex of each surface.

Statistics

For the comparison of demographic parameters between the normal-weight and obese groups, Wilcoxon rank sum tests were performed to determine whether there were significant group differences (P values $\leq .05$) for numeric parameters, while χ^2 tests were used for categorical parameters. To compare the cortical thickness between neonates born to normal-weight or obese mothers, we performed ANOVA with covariates of neonate sex and race, postmenstrual age at MR imaging, maternal age at pregnancy, as well as IQ and education for each cortical region defined by the UNC Neonatal Cortical Surface Atlas. Sex and postmenstrual age were controlled as potential confounders because infant brain differences associated with sex and gestational/postmenstrual age have been reported.^{34,35} Effects of maternal age and IQ were also controlled because of potential effects on the offspring's brain development or neurodevelopmental outcomes.³⁶ For family socioeconomic status, due to missing data in the father's education and parental income for several subjects, only maternal education was added as a covariate in the analysis. The cortical thickness was not normalized to total brain volume because the literature suggested that normalizing did not improve the discriminant and predictive performance of cortical thickness measures.³⁷ False discovery rate (FDR) correction was used for multiple-comparison correction associated with the 68 brain cortical regions evaluated in total, and regions with FDR-corrected P values $\leq .05$ were regarded as significant regarding cortical thickness. In addition, to investigate whether there is a linear relationship between maternal body composition and neonate brain development, we evaluated correlations between maternal fat mass percentage measured at ~12 weeks of gestation and neonate brain cortical thickness at ~2 weeks of postnatal age for those regions identified by ANOVA using the Spearman rank partial-correlation test. Partial correlation coefficients (R values) and significance levels (P values) were calculated, and those correlations with P values $\leq .05$ after controlling of neonate sex and race, postmenstrual age at MR imaging, maternal age at pregnancy, and IQ and education were regarded as significant. All statistics analyses were done in Matlab software, Version R2018b (MathWorks).

RESULTS

The normal-weight and obese pregnant women differed significantly in mean BMI measured at ~12 weeks of pregnancy (22.2 [SD, 1.9] versus 33.2 [SD, 1.5], $P < .001$), as well as in body fat

FIG 1. The anatomic locations for the 3 brain cortical regions that showed significant differences (FDR-corrected $P \leq .05$) in mean cortical thickness between neonates born to normal-weight-versus-obese women: the left pars opercularis (LPO) gyrus (A), the left pars triangularis (LPT) gyrus (B), and the left rostral middle frontal (LRMF) gyrus (C). The comparison of mean cortical thickness for these 3 regions in these groups of neonates is illustrated in D.

percentage (28.8% [SD, 4.2%] versus 44.0% [SD, 3.9%], $P < .001$). Other maternal/family measures such as maternal age at pregnancy and IQ as well as family socioeconomic status were not different (Table). For the neonates, there were no group differences in sex, race, birth weight/height, head circumference, gestational age at birth, or postmenstrual age at MR imaging (Table).

For comparison of cortical thickness at ~2 weeks' postnatal age for the neonates, the ANOVA analysis (with effects of neonate sex and race, postmenstrual age at MR imaging, maternal age at pregnancy, and IQ- and education-controlled) showed that there were 3 regions with significant differences (FDR-corrected, $P \leq .05$) between neonates born to normal-weight versus obese women in the 68 cortical regions defined by the UNC Neonatal Cortical Surface Atlas. Specifically, the mean cortical thickness in the left pars opercularis gyrus was higher in neonates born to normal-weight-versus-obese women (1.99 [SD, 0.07] mm versus 1.90 [SD, 0.07] mm; FDR-corrected, $P = .01$); the mean cortical thickness in the left pars triangularis gyrus was also higher in neonates born to normal-weight-versus-obese women (1.92 [SD, 0.07] mm versus 1.84 [SD, 0.06] mm; FDR-corrected, $P = .04$); and the mean cortical thickness in the left rostral middle frontal gyrus was also higher in neonates born to normal-weight-versus-obese women (1.78 [SD, 0.03] mm versus 1.74 [SD, 0.04] mm; FDR-corrected, $P = .04$). The anatomic location of these 3 cortical regions as well as the comparison of mean cortical thickness in these 3 regions are illustrated in Fig 1. No other regions showed differences in cortical thickness between the 2 neonate groups.

For the 3 cortical regions identified using the ANOVA analysis, the Spearman rank partial correlation test was used to evaluate whether there is a linear relationship between mother's body

composition (particularly body fat mass percentage) and the neonatal brain development (particularly cortical thickness). Similarly, neonate sex and race and postmenstrual age at MR imaging, as well as maternal age at pregnancy and IQ and education were controlled in the partial correlation analysis. There were significant negative correlations ($P < .05$) between maternal fat mass percentage and neonate brain cortical thickness in all of these 3 regions (Fig 2). Specifically, neonate brain regional mean cortical thickness measured at ~2 weeks' postnatal age negatively correlated with maternal body fat mass percentage measured at ~12 weeks of pregnancy in the left pars opercularis gyrus ($R = -0.34$, $P = .04$), the left pars triangularis gyrus ($R = -0.50$, $P = .001$), and the left rostral middle frontal gyrus ($R = -0.42$, $P = .01$).

DISCUSSION

Our study indicated significant relationships between the mother's BMI status and body composition at early

pregnancy and the neonate's brain cortical development at ~2 weeks of age. The more obese the pregnant women were during early pregnancy, the lower the cortical thickness was in several brain regions in their neonates. All pregnant women included in this study were healthy, without medical conditions or medication use during pregnancy that may affect fetal brain development, and all neonates were also healthy, born full-term, without any birth defects or medical conditions that may impact their brain development. Our results suggest that there may be a negative impact of maternal obesity during pregnancy on the offspring's brain development because cortical thickness increases during infancy in normal development and it appears that maternal obesity may have slowed or impaired cortical development at 2 weeks' postnatal age.

The brain regions showing the potential impact of maternal obesity on cortical development are all in the frontal lobe, indicating that frontal lobe brain regions may be most vulnerable to potential disturbances in fetal programming due to maternal obesity. This finding is consistent with previous findings that microstructure integrity evaluated by DTI was lower in widespread frontal white matter regions in neonates born to obese-versus-normal-weight mothers¹⁹ and that functional connectivity from the dorsal anterior cingulate cortex to the prefrontal network measured by resting-state fMRI was lower in neonates born to obese-versus-normal-weight mothers.²⁰ This is also consistent with another functional connectivity study of infants born to adolescents or young adult women that demonstrated that higher maternal BMI was associated with lower frontothalamic connectivity in the infant brain.²³ While the underlying and potential neurobiologic processes for the vulnerability of frontal lobe

FIG 2. Partial correlation analysis showed significant negative correlations ($P < .05$) between maternal body fat mass percentage measured at ~12 weeks of pregnancy and neonate brain mean cortical thickness measured at ~2 weeks' postnatal age in the left pars opercularis (LPO) gyrus, left pars triangularis (LPT) gyrus, and left rostral middle frontal (LRMF) gyrus.

development to maternal obesity are unclear, numerous studies have indicated that the rapid infant frontal brain development is sensitive to early environmental experiences,³⁸ including exposures to different adverse prenatal environmental factors.^{39,40}

For the 3 specific frontal lobe regions that showed decreased cortical thickness associated with maternal obesity, the left pars opercularis gyrus and the left pars triangularis gyrus form the middle and posterior parts of the left inferior frontal gyrus and are commonly regarded as the Broca area, which is important for expressive language function such as speech production. The left rostral middle frontal gyrus largely overlaps with the dorsolateral prefrontal cortex and is critical for executive function such as emotion regulation and working memory. Thinner cortices in these language- and executive function-related brain regions in early life may have important functional implications because recent studies have shown that maternal obesity is associated with lower composite language scores¹⁴ or a different language developmental trajectory,⁴¹ as well as lower cognitive flexibility⁴²

or poorer executive functioning in areas of attention, inhibition control, and working memory⁴³ in children.

Most interesting, frontal brain structural and functional changes have also been observed in children, associated with childhood obesity. For example, in recent analyses of National Institutes of Health Adolescent Brain and Cognitive Development Study data, increased BMI in 9- to 11-year-old children significantly correlated with reduced cortical thickness in the frontal lobe and lower performance in several tasks involving executive functions,⁴⁴ and reduced thickness in a number of frontal cortical regions partially accounted for reductions in executive function.⁴⁵ Many fMRI studies have also demonstrated differences in brain activation involving the frontal lobe during task performance between normal-weight and overweight/obese children/adolescents.⁴⁶⁻⁵⁰ Given that maternal obesity may predispose offspring to a higher risk of childhood obesity, the similarities of changes in the developing brain associated with maternal obesity and childhood obesity may suggest potential consequential effects, eg, maternal obesity may possibly program persistent changes in certain regions of the developing brain, which, in turn, may cause behavior issues in childhood (such as deficiency in inhibitory control toward food) and further increase the risk of developing childhood obesity. While this is a speculation that cannot be validated by the data in our current study alone (eg, whether there are persistent changes in the brain associated with maternal obesity that will require follow-up imaging studies), our results certainly can contribute to the growing field striving to understand more about obesity-brain relationships.

Our study design was prospective and longitudinal, and we recruited pregnant women in early pregnancy, measured their body composition, followed up their pregnancy, and evaluated their infants' brain development using MR imaging. Nevertheless, 1 limitation of our findings is that we only have complete MR imaging data for the cohort at neonatal age. Follow-up MR imaging and neurodevelopmental assessments at later ages will be necessary to determine whether brain changes associated with maternal obesity in neonates persist into later childhood and impact long-term neurodevelopmental outcomes. Another limitation is the relatively small sample size of this study. A larger-scale study may allow us to control for more potential confounders and may identify more brain regions and imaging features in the developing brain associated with maternal obesity. Last, family socioeconomic status may also be a confounding factor for infant brain development.

In our statistical analysis, we controlled for the mother's education, for which we have data for all subjects ($n = 44$). For other socioeconomic parameters for which we have missing data including the mother's income ($n = 37$) and the father's education ($n = 41$) and income ($n = 40$), we compared the available data, and there were no group differences (Table). In addition, the significant group differences as well as significant correlations between maternal body fat mass percentage and neonate cortical thickness in the 3 regions we report still hold (all P values in Figs 1D and 2 are still $< .05$ except for one) if we add parental incomes and the father's education as additional covariates in the data analysis (despite the missing data and the relatively large number of covariates compared with the sample size in the statistical model).

CONCLUSIONS

Neonates born to obese women showed lower cortical thickness measured by MR imaging at ~2 weeks of age in several frontal brain regions important for language and executive function. The mother's body fat mass percentage measured in early pregnancy negatively correlated with the neonate's brain cortical thickness in these regions. Our results indicate that there may be a negative impact of maternal obesity during pregnancy on the offspring's cortical brain development.
